# C-GLISp: Preference-Based Global Optimization Under Unknown Constraints With Applications to Controller Calibration

Mengjia Zhu<sup>®</sup>, Member, IEEE, Dario Piga<sup>®</sup>, Member, IEEE, and Alberto Bemporad<sup>®</sup>, Fellow, IEEE

Abstract—Preference-based global optimization algorithms minimize an unknown objective function only based on whether the function is better, worse, or similar for given pairs of candidate optimization vectors. Such optimization problems arise in many real-life examples, such as finding the optimal calibration of the parameters of control law. The calibrator can judge whether a particular combination of parameters leads to a better, worse, or similar closed-loop performance. Often, the search for the optimal parameters is also subject to unknown constraints. For example, the vector of calibration parameters must not lead to closed-loop instability. This article extends an active preference learning algorithm introduced recently to handle unknown constraints. The proposed method, called C-GLISp, looks for an optimizer of the problem only based on preferences expressed on pairs of candidate vectors and on whether a given vector is reported feasible and/or satisfactory. C-GLISp learns a surrogate of the underlying objective function based on the expressed preferences and a surrogate of the probability that a sample is feasible and/or satisfactory based on whether each of the tested vectors was judged as such. The surrogate functions are used iteratively to propose a new candidate vector to test and judge. Numerical benchmarks and a semiautomated control calibration task demonstrate the effectiveness of C-GLISp, showing that it can reach near-optimal solutions within a small number of iterations.

Index Terms—Active preference learning, global optimization with unknown constraints, model predictive control (MPC).

#### I. INTRODUCTION

CTIVE learning algorithms for black-box global optimization problems have been studied since the 1960s under different names [1]–[4]. These algorithms solve the problem by optimizing a surrogate of the objective function, which is estimated by exploring the space of the optimization variables. In particular, nowadays, Bayesian optimization (BO) [5] is widely used to solve problems in which the cost function can only be quantified after running an

experiment, such as in experimental controller calibration [6] and automated machine learning [7]. The main idea of such methods is to fit a surrogate function to the available observations and iteratively suggest the next query point by optimizing an acquisition function. The latter trades off between exploiting the surrogate function to improve the objective and scouting unexplored areas of the search domain. An alternative surrogate method to BO based on estimating the underlying objective by radial basis functions (RBFs) and inverse distance weighting (IDW) for exploration, called GLIS, was recently proposed in [8].

Successful applications of global optimization algorithms based on active learning for the calibration of model predictive control (MPC), proportional-integral-derivative (PID), and state-feedback control laws were presented in [9]–[12]. In this context, the tuning parameters of the controller are the optimization variables, and a quantitative characterization of the resulting closed-loop performance after running a simulation or experiment is the objective to optimize. These algorithms were also used for model selection [13], [14], for controller tuning in robotic manipulation and trajectory tracking [15]–[17], in optimizing gait parameters in robotic bipedal locomotion [18], and for "safe" optimization of position controller parameters of quadrotors [19].

A limitation of black-box optimizers, such as BO and GLIS, is that they require quantifying an objective function after running an experiment. However, many real-world controller calibration problems involve multiple objectives to optimize, such as settling time, overshoots, actuation effort, computational burden, and other performance-related metrics. The relative weights of such objectives can be hard to assign and sometimes even impossible to quantify, as they are the result of a qualitative judgment. On the other hand, a skilled calibrator can often assess the closed-loop performance of certain tuning combinations in terms of "this test was better than the other one," i.e., by pairwise comparisons. Thus, when quantifying an objective function is difficult or impossible, one can instead use these expressed preferences to learn an underlying surrogate function to be optimized, which leads to the area of preference-based learning algorithms.

Preference-based Bayesian optimization (PBO) has been proposed in [20]–[23]. Preference-based reinforcement learning (RL) has also drawn much attention in recent years [24]. The reader is referred to the survey paper [25] for a comprehensive review. Note that sample efficiency, which

is related to the credit assignment task in RL, is a major challenge in many preference-based RL methods [25]. A more sample-efficient active preference learning method, called GLISp (an extension of GLIS), was proposed in [26]. GLISp learns a surrogate of the underlying preference relations by solving a quadratic programming (QP) problem, whose constraints reflect the expressed preference on whether a specific candidate is better than the other. Then, the algorithm iteratively proposes a new candidate for testing to the decisionmaker for comparison. This experiment-driven preferencebased approach was tested in [27] for semiautomated MPC calibration (automatic selection of control parameters and manual assessment of performance by comparisons), demonstrating its effectiveness in terms of the number of experiments needed to reach a near-optimal closed-loop performance.

Real-life control design problems often involve constraints that are unknown beforehand, or for which it is not possible to find an explicit analytic expression. This is a challenge since safe exploration can be essential in many control applications, and infeasible experiments can be dangerous and costly. Several methods have been proposed in the literature to handle unknown constraints and encourage safe exploration. Sui et al. [28] presented a stagewise safe BO with Gaussian processes, which they later extended to allow multiple safety constraints independent of the objective function [29]. A general formulation for constrained BO and a modified version of the expected improvement acquisition function was illustrated in [30], which handles noisy constraint observations and considers cases in which the objective and constraint functions are decoupled. In [31], a sequential model-based optimization method was proposed. The unknown feasible region boundaries are first reconstructed from data through support vector machines (SVMs). Then, a global optimization step is performed via BO. Differently from the aforementioned methods, GLISp accounts for unknown constraints implicitly in the preferences expressed by the decision-maker by making the samples that are infeasible lose the pairwise comparisons against the feasible ones.

This article extends GLISp to handle unknown constraints in the active learning phase explicitly, therefore encouraging safe exploration. Besides expressing preferences, the decision-maker is asked to label an experiment as feasible and if its outcome is overall satisfactory (yes/no). Based on such labels, a surrogate of the probability of constraint feasibility and experiment's satisfaction is learned via an IDW interpolant function [8]. The surrogates are properly integrated within the acquisition function to find the next point to test. We show the efficiency and effectiveness of the proposed method, called C-GLISp, in three numerical benchmarks and on an extension of the case study originally proposed in [27] on semiautomated MPC calibration for autonomous driving. MATLAB and Python implementations of C-GLISp are also provided and available at http://cse.lab.imtlucca.it/ bemporad/glis.

The rest of this article is organized as follows. The problem of preference-based optimization with unknown constraints is formulated in Section II. The proposed active learning algorithm and details for its practical implementation are discussed in Section III. Numerical benchmarks showing the properties and the effectiveness of the proposed method are reported in Section IV, while the case study on semiautomated MPC calibration for autonomous driving is presented in Section V. Conclusions and directions for future research are drawn in Section VI.

#### II. PROBLEM FORMULATION

Let  $\mathcal{D} \subseteq \mathbb{R}^{n_x}$  be the space of decision vectors x. We are interested in minimizing an (unknown) objective function  $f: \mathcal{D} \to \mathbb{R}$  subject to the constraint that x belongs to an (unknown) feasibility set  $\Omega_G \subseteq \mathcal{D}$ .

We assume that we cannot represent the set  $\Omega_G$ , but rather that, given a vector  $x \in \mathcal{D}$ , a decision-maker can assess the value of the feasibility function  $G : \mathcal{D} \to \{0, 1\}$  defined as

$$G(x) = \begin{cases} 0, & \text{if } x \notin \Omega_G \\ 1, & \text{if } x \in \Omega_G. \end{cases}$$
 (1)

In other words, a value x outside  $\Omega_G$  will be considered as "unacceptable" (G(x) = 0) by the decision-maker. For example, an unacceptable x can be a set of controller parameters leading to an unstable closed-loop behavior or to a control law that is too expensive to compute in real time.

Furthermore, we assume that the objective function f cannot be directly quantified, but rather that can be indirectly observed in two ways.

1) For a given sample  $x \in \mathcal{D}$ , the decision-maker is requested to say whether or not x leads to certain "satisfactory performance." Formally, we can define a satisfaction set  $\Omega_S \subseteq \mathcal{D}$  and a satisfaction function  $S: \mathcal{D} \to \{0, 1\}$  as

$$S(x) = \begin{cases} 0, & \text{if } x \notin \Omega_S \\ 1, & \text{if } x \in \Omega_S \end{cases}$$
 (2)

where the set  $\Omega_S$  contains all the vectors x leading to a performance that the decision-maker judges satisfactory. An analytic expression of  $\Omega_S$  is therefore not available, and only the value S(x) is provided by the decision-maker for any given  $x \in \mathcal{D}$ . Note that  $\Omega_S$  may not be a subset of  $\Omega_G$ , for example, when the preference-based optimization process is carried out in simulation: a sample may lead to satisfactory performance but would not be implementable due to hardware limitations. On the other hand, in cases of assessments based on physical experiments,  $\Omega_S$  is necessarily a subset of  $\Omega_G$ , as no performance would be available for evaluation when the parameters are infeasible.

2) For any pair  $x_1, x_2 \in \mathcal{D}$ , the decision-maker is requested to provide the output of the preference function:  $\pi : \mathcal{D} \times \mathcal{D} \to \{-1, 0, 1\}$ 

$$\pi(x_1, x_2) = \begin{cases} -1, & \text{if } x_1 \text{ "better" than } x_2 \\ 0, & \text{if } x_1 \text{ "as good as" } x_2 \\ 1, & \text{if } x_2 \text{ "better" than } x_1 \end{cases}$$
 (3)

where the preference in (3) is implicitly defined according to the underlying hidden function f to be

minimized, namely

$$\pi(x_1, x_2) = \begin{cases} -1, & \text{if } f(x_1) < f(x_2) \\ 0, & \text{if } f(x_1) = f(x_2) \\ 1, & \text{if } f(x_1) > f(x_2). \end{cases}$$
(4)

The rationale behind the above problem formulation is that often one encounters practical decision problems in which a function f is impossible to quantify, but anyway, it is possible for a human operator to express a qualitative evaluation (e.g., "good" or "bad") and a preference between the outcome of two experiments.

Formally, we want to find the optimal solution  $x^* \in \Omega_S \cap \Omega_G$  such that  $x^*$  is "better" (or "no worse") than any other x according to the preference function  $\pi$ , i.e.,

find 
$$x^*$$
 such that  $\pi(x^*, x) \le 0 \ \forall x \in \Omega_S \cap \Omega_G$ . (5)

We propose to solve problem (5) iteratively as follows: 1) suggest a sequence of decision vectors  $x_1, \ldots, x_N \in \mathcal{D}$  to test; 2) ask to evaluate the feasibility function  $G(x_i)$  and the satisfaction function  $S(x_i)$  for  $i = 1, \ldots, N$ ; and 3) ask to evaluate the preference function  $\pi(x_i, x_j)$  for M given pairs  $(i, j), i, j = 1, \ldots, N, i \neq j$ , where M is the number of expressed preferences,  $1 \leq M \leq \binom{N}{2}$ . The goal is to propose candidate vectors  $x_N$  approaching the optimal solution  $x^*$  as N grows.

#### III. PROPOSED METHOD

The proposed preference-based optimization method to solve problem (5) is based on an extension of the GLISp algorithm originally introduced in [26]. We refer to the new algorithm as C-GLISp, whose aim is to handle unknown constraints expressed in terms of an approximation of the feasibility function G in (1) and the satisfaction function S in (2).

Similar to GLISp, C-GLISp involves two main phases: an initial random sampling and an active learning phase. In both phases, C-GLISp trains and updates three surrogate functions approximating the feasibility function G, the satisfaction function S, and the underlying function f. During the active learning phase, the next point for evaluation is selected by optimizing an acquisition function, which trades off exploitation (optimization only based on the surrogates describing the observed preferences and constraints) and exploration (searching unexplored areas of the domain  $\mathcal{D}$ ). The goal of C-GLISp is to approach an optimal solution  $x^*$  as in (5) within a small number N of experiments.

## A. Learning Unknown Constraint Functions

We discuss how to train surrogates of the functions G and S that approximate, respectively, the feasibility constraint  $x \in \Omega_G$  and the satisfaction constraint  $x \in \Omega_S$ . The idea is to ask the decision-maker to assess, once an experiment is performed, whether the constraints  $x \in \Omega_G$  and  $x \in \Omega_S$  are satisfied or not, and train surrogate functions of G and S based on the outcome of S 2 of such queries. These queries are performed on a set of samples S 1, ..., S 1 iteratively proposed by C-GLISp.

Compared to unconstrained preference-based optimization such as GLISp, in which an infeasible/unsatisfactory sample only indirectly reveals itself as such by losing pairwise comparisons against feasible/satisfactory ones, C-GLISp exploits the information on whether  $x \in \Omega_G$  and/or  $x \in \Omega_S$  to facilitate the optimization process, in particular, to avoid exploring the infeasible and/or unsatisfactory region and therefore reduce the number of samples  $x_i \notin \Omega_G$  and/or  $x_i \notin \Omega_S$ .

The surrogate functions for G and S are constructed as follows. The decision-maker observes the outcome of the performed experiments, and he/she provides a feasibility vector  $G_F = [G_1, \ldots, G_N]' \in \{0, 1\}^N$  with

$$G_i = G(x_i) \tag{6}$$

and a satisfaction vector  $S_F = [S_1, \dots, S_N]' \in \{0, 1\}^N$  with

$$S_i = S(x_i) \tag{7}$$

by assessing whether each experiment is feasible and satisfactory. Then, surrogates  $\hat{G}$  of G and  $\hat{S}$  of S are constructed from the observations  $G_F$  and  $S_F$ , respectively, as detailed next.

A surrogate function  $\hat{G}: \mathcal{D} \to \mathbb{R}$  predicting the probability of satisfying the feasibility constraint  $x \in \Omega_G$  is defined as

$$\hat{G}(x) = \sum_{i=1}^{N} \nu_i(x) G_i \tag{8}$$

where  $v_i(x): \mathcal{D} \to \mathbb{R}$  for i = 1, ..., N is defined as

$$v_{i}(x) = \begin{cases} 1, & \text{if } x = x_{i} \\ 0, & \text{if } x = x_{j}, j \neq i \\ \frac{w_{i}(x)}{\sum_{i=1}^{N} w_{i}(x)}, & \text{otherwise.} \end{cases}$$
(9)

Here,  $w_i : \mathcal{D} \setminus \{x_i\} \to \mathbb{R}$  is the following IDW function [32]:

$$w_i(x) = \frac{e^{-d^2(x,x_i)}}{d^2(x,x_i)} \tag{10}$$

where  $d: \mathcal{D} \times \mathcal{D} \to \mathbb{R}$  denotes the squared Euclidean distance

$$d(x, x_i) = \|x - x_i\|_2^2.$$
 (11)

The surrogate function  $\hat{S}: \mathcal{D} \to \mathbb{R}$  is defined similarly. The approach presented in this article aims at solving problems where experiments are expensive to run so that data efficiency is essential. IDW interpolation functions are selected in this case because of their high accuracy. Other binary classification methods (e.g., logistic regression or random forests) would be less suitable in this context since their accuracy with a small number of training data is limited. SVMs [33] can be a potential substitute since they work well with small-and medium-size training sets. However, our numerical tests have shown that IDW interpolation functions outperform SVM. In addition, the functions  $\hat{G}$  and  $\hat{S}$  generated by IDW interpolation are always between 0 and 1 by construction (see [8, Lemma 1-P2]) and can be interpreted as probabilities of being feasible/satisfactory.

#### B. Learning the Preference Function

RBFs [34], [35] are flexible and have been adopted to solve global optimization problems in [8] and [34]–[37] with success. Therefore, as in [26], we parameterize the surrogate function  $\hat{f}: \mathcal{D} \to \mathbb{R}$  as a linear combination of RBFs [34], [35]

$$\hat{f}(x) = \sum_{k=1}^{N} \beta_k \phi(\epsilon d(x, x_i))$$
 (12)

where  $\phi: \mathbb{R} \to \mathbb{R}$  is an RBF,  $\epsilon > 0$  is a scalar hyperparameter defining the shape of the RBF, and  $\beta = [\beta_1, \ldots, \beta_N]^T$  are the unknown coefficients to be determined. Some RBFs commonly used are  $\phi(\epsilon d) = (1/(1 + (\epsilon d)^2))$  (inverse quadratic),  $\phi(\epsilon d) = e^{-(\epsilon d)^2}$  (Gaussian), and  $\phi(\epsilon d) = (\epsilon d)^2 \log(\epsilon d)$  (thin plate spline).

Besides the feasibility vector  $G_F$  and the satisfaction vector  $S_F$ , the preference vector  $B = [b_1, \dots, b_M]^T \in \{-1, 0, 1\}^M$  is also assumed to be provided by the decision-maker with

$$b_h = \pi(x_{i(h)}, x_{j(h)}) \tag{13}$$

for  $x_i$ ,  $x_j \in \mathcal{D}$  such that  $x_i \neq x_j$ ,  $\forall i \neq j$ , i, j = 1, ..., N. Here, M is the number of expressed preferences,  $1 \leq M \leq \binom{N}{2}$ ,  $h \in \{1, ..., M\}$  is the index enumerating the preferences, and  $i(h), j(h) \in \{1, ..., N\}$ ,  $i(h) \neq j(h)$ .

The preferences  $b_h$  expressed by the decision-maker are used to shape the surrogate objective function  $\hat{f}$  by imposing the following constraints:

$$\hat{f}(x_{i(h)}) \leq \hat{f}(x_{j(h)}) - \sigma \text{ if } b_h = -1$$

$$\hat{f}(x_{i(h)}) \geq \hat{f}(x_{j(h)}) + \sigma \text{ if } b_h = 1$$

$$|\hat{f}(x_{i(h)}) - \hat{f}(x_{j(h)})| \leq \sigma \text{ if } b_h = 0$$
(14)

for h = 1, ..., M, where  $\sigma > 0$  is a given scalar that avoids the trivial solution  $\hat{f}(x) \equiv 0$ .

Similar to SVMs [33], the vector  $\beta$  of coefficients describing the surrogate  $\hat{f}$  is obtained by solving the following convex QP problem:

$$\min_{\beta,\varepsilon} \sum_{h=1}^{M} c_h \varepsilon_h + \frac{\lambda}{2} \sum_{k=1}^{N} \beta_k^2$$
s.t. 
$$\sum_{k=1}^{N} \beta_k (\phi(\epsilon d(x_{i(h)}, x_k)) - \phi(\epsilon d(x_{j(h)}, x_k)))$$

$$\leq -\sigma + \varepsilon_h \quad \forall h : b_h = -1$$

$$\sum_{k=1}^{N} \beta_k (\phi(\epsilon d(x_{i(h)}, x_k)) - \phi(\epsilon d(x_{j(h)}, x_k)))$$

$$\geq \sigma - \varepsilon_h \quad \forall h : b_h = 1$$

$$\left| \sum_{k=1}^{N} \beta_k (\phi(\epsilon d(x_{i(h)}, x_k)) - \phi(\epsilon d(x_{j(h)}, x_k))) \right|$$

$$\leq \sigma + \varepsilon_h \quad \forall h : b_h = 0$$

$$h = 1, \dots, M \tag{15}$$

that captures the preference relationships in (14) and the parametrization of  $\hat{f}$  in (12). In (15),  $c_h$  are positive weights and  $\varepsilon_h$  are positive slack variables used to relax the constraints imposed by (14). The violation of the imposed constraints

could be caused by an inappropriate selection of the RBF, leading to poor flexibility in the parametric description of the surrogate function  $\hat{f}$  and by inconsistent assessments provided by the decision-maker. The scalar  $\lambda > 0$  in the cost function (15) is a regularization parameter. With  $\lambda > 0$ , problem (15) is a QP problem that admits a unique solution.

In the constrained preference-based optimization algorithm detailed in Section III-C, we will execute K-fold cross validation periodically (i.e., when i is in the predefined self-calibration index set  $\mathcal{I}_{sc} \subseteq \{1, \ldots, N_{max} - 1\}$ ) to automatically tune the hyperparameter  $\epsilon$  defining the shape of the RBF in (12) during the active learning phase, as recommended in [26].

## C. Acquisition Function

Minimizing  $\hat{f}$  greedily to generate the next sample  $x_{N+1}$  may lead the solver to converge to a point that is not the global optimum of (5). Hence, when selecting the next point  $x_{N+1}$ , besides exploiting the surrogate  $\hat{f}$ , some exploration should be considered to search regions with limited/no samples to reduce the uncertainty associated with  $\hat{f}$ . Also, the feasibility and satisfactory regions are unknown and are only implicitly included in the surrogate function  $\hat{f}$ . Therefore, we also include terms to explicitly avoid the exploration in the regions with low probabilities of being feasible and satisfactory by penalizing the (estimated) infeasibility  $x \notin \Omega_G$  and unsatisfactory performance  $x \notin \Omega_S$ .

The exploration term used in GLISp is the following IDW function:  $z: \mathcal{D} \to \mathbb{R}$ 

$$z(x) = \begin{cases} 0, & \text{if } x \in \{x_1, \dots, x_N\} \\ \tan^{-1} \left(\frac{1}{\sum_{i=1}^{N} r_i(x)}\right), & \text{otherwise} \end{cases}$$
 (16)

where  $r_i(x) = (1/d^2(x, x_i))$ . Note that z(x) = 0 for all the decision variables x already sampled and tested, and z(x) > 0 in  $\mathcal{D} \setminus \{x_1, \dots, x_N\}$ . The arc tangent function is used to prevent the new sampled point from getting excessively far away from the existing ones.

Unlike GLISp, here, we modify (16) into

$$z_{N}(x) = \left(1 - \frac{N}{N_{\text{max}}}\right) \tan^{-1} \left(\frac{\sum_{i=1}^{N} r_{i}(x_{N}^{*})}{\sum_{i=1}^{N} r_{i}(x)}\right) + \frac{N}{N_{\text{max}}} \tan^{-1} \left(\frac{1}{\sum_{i=1}^{N} r_{i}(x)}\right)$$
(17)

for  $x \notin \{x_1, \ldots, x_N\}$  and  $z_N(x) = 0$  otherwise. In (17),  $x_N^*$  is the best decision variable found up to iteration N. In (17),  $N_{\text{max}}$  is the maximum allowed number of experiments. The rationale behind (17) is that it encourages the exploration of regions of  $\mathcal{D}$  further away from the current best solution in the early iterations and reduces its effects as the number N of experiments increases. The exploration function in (17) was empirically observed to better escape from local minima than that in (16).

The acquisition function  $a: \mathcal{D} \to \mathbb{R}$  is defined as

$$a(x) = \frac{\hat{f}(x)}{\Lambda \hat{F}} - \delta_E z_N(x) + \delta_G (1 - \hat{G}(x)) + \delta_S (1 - \hat{S}(x)) \tag{18}$$

where  $\delta_E \geq 0$  is the exploration parameter and  $\delta_G$ ,  $\delta_S \geq 0$  weight the probability of a sample x to be infeasible and/or unsatisfactory. The term  $\Delta \hat{F} = \max_i \{\hat{f}(x_i)\} - \min_i \{\hat{f}(x_i)\}$  is the range of the surrogate function  $\hat{f}$  on the samples in  $\{x_1, \ldots, x_N\}$ . It is used as a scaling factor in (18) to make each term in (18) comparable, which eases the selection of the hyperparameters  $\delta_E$ ,  $\delta_G$ , and  $\delta_S$ .

The exploration parameter  $\delta_E$  encourages sampling unexplored regions of the domain  $\mathcal{D}$ . Setting  $\delta_E=0$  makes C-GLISp relying heavily on the accuracy of the surrogate functions  $\hat{f}$ ,  $\hat{G}$ , and  $\hat{S}$ , which may easily lead to missing the global optimum. On the other hand, setting  $\delta_E\gg 1$  leads C-GLISp to explore the entire domain  $\mathcal{D}$  regardless of the decision-maker's preferences and feasibility/satisfaction assessments.

Functions  $\hat{G}$  and  $\hat{S}$  in (18) aim at discouraging exploration in regions where the experiment is predicted to be infeasible (i.e.,  $x \notin \Omega_G$ ) and/or unsatisfactory (i.e.,  $x \notin \Omega_S$ ). Therefore, a poor selection of the hyperparameters  $\delta_G$  and  $\delta_S$  and/or a poor predictive capability of  $\hat{G}$  and  $\hat{S}$  (e.g., due to a limited number of samples) can prevent finding new vectors that are actually feasible and/or satisfactory. To alleviate this issue, we suggest to adaptively tune  $\delta_G$  and  $\delta_S$  based on the sampled standard deviation obtained from leave-one-out cross validation [38] of  $\hat{G}$  and  $\hat{S}$ , respectively. More specifically, each available sample in the set  $\{x_1, \ldots, x_N\}$  is used once as a testing point and the remaining ones are used to train  $\hat{G}$ and  $\hat{S}$ . The prediction  $\hat{G}(x_i)$  and  $\hat{S}(x_i)$  on the test sample  $x_i$ is compared with the corresponding labels  $G(x_i)$  and  $S(x_i)$ assigned by the decision-maker to compute the following sampled standard deviations of the error:

$$\hat{\sigma}_{G} = \min \left\{ 1, \sqrt{\frac{\sum_{i=1}^{N} (\hat{G}(x_{i}) - G(x_{i}))^{2}}{N - 1}} \right\}$$

$$\hat{\sigma}_{S} = \min \left\{ 1, \sqrt{\frac{\sum_{i=1}^{N} (\hat{S}(x_{i}) - S(x_{i}))^{2}}{N - 1}} \right\}. \tag{19}$$

The sampled standard deviations are then used to update, after each iteration, the weights  $\delta_G$  and  $\delta_S$  as follows:

$$\delta_G = (1 - \hat{\sigma}_G)\delta_{G,\text{default}} \tag{20a}$$

$$\delta_S = (1 - \hat{\sigma}_S)\delta_{S,\text{default}} \tag{20b}$$

where  $\delta_{G,\text{default}}$  and  $\delta_{S,\text{default}}$  are default values set by the user. Clearly, one should select  $\delta_{G,\text{default}} > \delta_{S,\text{default}}$  so that infeasibility is penalized more than unsatisfactory behavior. The updated values of  $\delta_G$  and  $\delta_S$  are then used to construct the acquisition function a(x) in (18).

The next sample  $x_{N+1}$  to test is obtained by minimizing a(x), i.e.,

$$x_{N+1} = \arg\min_{x \in \mathcal{D}} a(x). \tag{21}$$

Different optimization methods can be used to solve problem (21) efficiently either via derivative-free [39] or derivative-based algorithms.

C-GLISp updates the surrogates  $\hat{f}$ ,  $\hat{G}$ , and  $\hat{S}$ , and the exploration function  $z_N(x)$ , by iteratively suggesting a new point  $x_{N+1}$  to test and by receiving feedback from the

**Algorithm 1** C-GLISp: Preference Learning Algorithm With Unknown Constraint Handling

**Input**: Lower and upper bounds  $(\ell,u)$ , known constraint set if available; number  $N_{\text{init}} \geq 2$  of initial samples, number  $N_{\text{max}} \geq N_{\text{init}}$  of maximum function evaluations;  $\delta_E \geq 0$ ,  $\delta_{G,\text{default}} \geq 0$  and  $\delta_{S,\text{default}} \geq 0$ ;  $\sigma > 0$ ; and  $\epsilon > 0$ ; self-calibration index set  $\mathcal{I}_{\text{sc}} \subseteq \{1,\dots,N_{\text{max}}-1\}$ .

- 1. Generate  $N_{\text{init}}$  random samples  $X = \{x_1, \dots, x_{N_{\text{init}}}\}$  using Latin hypercube sampling method [40];
- 2.  $N \leftarrow 1, i^{\star} \leftarrow 1$ ;
- 3. While  $N < N_{\rm max}$  do
- 3.1. **if** N = 1 **then** 
  - 3.1.1. Observe feasibility  $G_N$  and satisfaction  $S_N$ ;
- 3.2. if  $N \geq N_{\text{init}}$  then
  - 3.2.1. if  $N \in \mathcal{I}_{sc}$  then recalibrate  $\epsilon$  through K-fold cross-validation;
  - 3.2.2. Solve (15) to obtain  $\beta$  to define the surrogate function  $\hat{f}$  (12);
  - 3.2.3. Update  $\delta_G$  and  $\delta_S$  as in (20);
  - 3.2.4. Define acquisition function a as in (18);
  - 3.2.5. Solve optimization problem (21) and get  $x_{N+1}$ ;
- 3.3.  $i(N) \leftarrow i^*, j(N) \leftarrow N + 1;$
- 3.4. Observe feasibility  $G_{j(N)}$ , satisfaction  $S_{j(N)}$  and preference  $b_N = \pi(x_{i(N)}, x_{j(N)})$ ;
- 3.5. if  $b_N = 1$  then set  $i^* \leftarrow j(N)$ ;
- 3.6.  $N \leftarrow N + 1$ ;
- 4. End.

**Output**: Computed best input  $x^* = x_{i^*}$ .

decision-maker in terms of feasibility, overall satisfaction, and preferences between pairs of experiments. Algorithm 1 summarizes the proposed method.

## IV. OPTIMIZATION BENCHMARKS

We test C-GLISp on three constrained global optimization benchmarks to illustrate its effectiveness in solving optimization problems with unknown constraints. Computations are performed on an Intel i7-8550U 1.8-GHz CPU laptop with 8 GB of RAM. The Latin hypercube sampling method [40] (lhsdesign function of the Statistics and Machine Learning Toolbox of MATLAB [44]) is used in the initial sampling phase of C-GLISp. Particle swarm optimization (PSO) [45] is used to minimize the acquisition function as in (21).

C-GLISp is compared to the original GLISp and PBO (with expected improvement as acquisition function) [21, Sec. 2.3]. For numerical benchmarks, C-GLISp, GLISp, and PBO assign the preferences on pairwise comparisons based on the combined assessments of the objective function value, feasibility, and performance satisfaction. For each test function, depending on the problem formulation, a maximum of three types of queries is obtained when using C-GLISp, which are the preference relation (B), the feasibility label ( $G_F$ ), and the satisfaction label ( $S_F$ ). In contrast, GLISp and

a- The median of computed constrained optima that are feasible out of 100 runs (the distribution over 100 runs is reported in Table IV).

PBO only rely on the preference relation *B*. The goal of the comparison between C-GLISp and GLISp is to check whether accounting the feasibility and/or satisfactory information explicitly in the acquisition function can encourage safe exploration from the comparisons. It is worth noting that the exact evaluation of the objective function and the constraints (feasibility and satisfactory outcomes) for these numerical benchmarks are unknown to the algorithms and are only used to construct a synthetic decision-maker.

Table I lists the specifications of the benchmarks. The original feasibility set of the test function Mishra's Bird function-constrained (MBC) [41], [42] is modified so that the unconstrained global optimum in the search domain is no longer in the feasible area. The camelsixhumpshard constrained (CHC) benchmark [8], [43] considers two feasibility constraints, and the unconstrained global optimum also differs from the constrained one. Finally, the benchmark function camelsixhumps-hard and soft constrained (CHSC) [8], [43] has both feasibility and satisfaction constraints. The two unconstrained optima for this test function are both feasible but not satisfactory.

The values of the hyperparameters in C-GLISp, GLISp, and PBO are provided in Table II. The number of initial samples ( $N_{\rm init}$ ) is selected as one fourth of the maximum number of function evaluations ( $N_{\rm max}/4$ ) rounded to the nearest integer. Threefold cross validation is used to update

the hyperparameter  $\epsilon$  (12) at iterations  $N_{\rm init}$ ,  $N_{\rm init}$  + ( $N_{\rm max}$  –  $N_{\rm init}$ )/4,  $N_{\rm init}$  + ( $N_{\rm max}$  –  $N_{\rm init}$ )/2, and  $N_{\rm init}$  + 3( $N_{\rm max}$  –  $N_{\rm init}$ )/4, rounded to the closest integers, which defines the self-calibration index set  $\mathcal{I}_{\rm sc}$ . The tolerance  $\sigma$  in (15) is set to  $1/N_{\rm max}$ . The default value  $\delta_{G,{\rm default}}$  in (20) is the same as  $\delta_E$  so that the feasibility term in (18) is comparable to the pure exploration term, while the default value  $\delta_{S,{\rm default}}$  is selected as  $\delta_{G,{\rm default}}/2$  to reduce its effects with respect to hard feasibility constraints. The parameters  $\delta_G$  and  $\delta_S$  are kept at their default values during the first  $N_{\rm init}$  experiments and then updated each time a new point is added using (20). The remaining parameters of the solvers are set according to the defaults used or suggested in [26].

Table III reports the results obtained by running a Monte Carlo simulation with 100 runs of C-GLISp, GLISp, and PBO to obtain statistically significant results. One of such runs of C-GLISp on all three numerical benchmarks is shown in Fig. 1. Table IV shows the distribution over 100 runs of the percentage difference between the achieved feasible solutions and the true constrained optimum. Overall, the results from Tables III and IV show that C-GLISp can find a feasible near-optimal solution more frequently than GLISp and PBO.

From the results on the benchmark function MBC, where the feasibility set  $\Omega_G$  covers roughly one-third of the domain  $\mathcal{D}$  (cf. Fig. 1), the performance of GLISp and C-GLISp is comparable. They always terminate the search with a feasible

b- Number of runs whose computed optimizers are feasible out of 100 runs. Values in parentheses indicate the number of runs the optimizer is satisfactory.

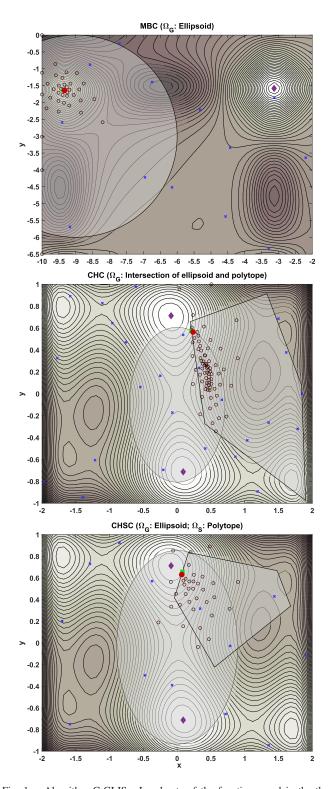

Fig. 1. Algorithm C-GLISp. Level sets of the functions used in the three benchmarks, along with feasibility and satisfaction sets. Blue  $\times$ : points generated from the initial sampling phase. Black  $\circ$ : points generated from the active learning phase. Purple  $\diamondsuit$ : global unconstrained optimizer. Red  $\bullet$ : constrained optimizer found after  $N_{\text{max}}$  iterations. Green  $\square$ : global constrained optimizer. As N increases, the points generated by the C-GLISp approach the constrained optimizer, and most of the points generated during the active learning phase lay in the feasibility and satisfaction regions.

optimum (100 out of 100 runs), with 67% and 69% of them, respectively, located within 5% difference from the global

	C-GLISp	43	22	13	16		

Note: only the runs with feasible solutions within 100% difference from the global optimum are counted.

solution (Table IV). On the other hand, PBO computes a feasible optimum in 91 runs, but with only around 39% within 5% difference (Table IV). When the constraint is more complex such as the one in CHC, the majority of the optima computed by C-GLISp (96 out of 100 runs) are feasible. In comparison, only 66 and 33 runs by GLISp and PBO, respectively, terminate with a feasible solution (Table III and Fig. 2). From Fig. 1, it is also observed that, for the test function CHC, after the initial sampling phase, most points generated in the active learning phase by C-GLISp are within the feasible region.

For the test function CHSC, C-GLISp often finds a nearoptimal solution that is both feasible and satisfactory. The performance of GLISp is slightly worse than C-GLISp in terms of the number of times a feasible and satisfactory solution is obtained. PBO can identify a feasible and satisfactory solution with a relatively high chance but still lower than both C-GLISp and GLISp. Also, its final outcome is worse (see Table III).

Table III also shows that, within the same number of iterations, the median of the computed feasible constrained optima from GLISp is always closer to the global constrained optimum than the one computed from C-GLISp. This is because of the tradeoff between trying to get a more accurate solution (which is often achieved by sampling multiple points close to the current best solution up to iteration N) and exploring a larger area to reduce uncertainty (in problems with unknown constraints, C-GLISp also tries to identify possible feasible regions).

For our problem setting, we set a limit on the computational budget. Modification of the exploration term from (16) to (17) helps to better escape from local minima in the early iterations by encouraging the exploration of regions of  $\mathcal{D}$  further away from the current best solution. This modification is significant for problems with small feasible regions (relative to the search domain) and/or complex unknown constraints (e.g., numerical benchmark CHC). This is because the additional exploration introduced by the modification can help the solver identify the feasible region more quickly and start recommending feasible guesses faster, reducing the chance that the solver gets trapped into an infeasible local optimum.

From the number of feasible solutions computed shown in Table III and the computed optimizers shown in Fig. 2,

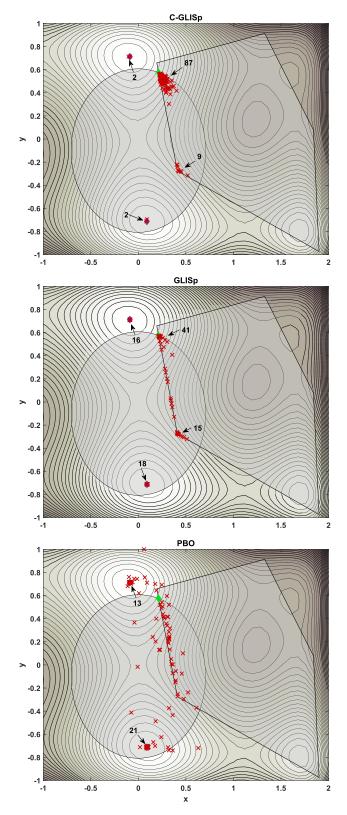

Fig. 2. Benchmark CHC. Optimizers computed by C-GLISp, GLISp, and PBO in 100 runs. Red ×: optimizer computed at the end of each run. Purple ♦: unconstrained optimizer. Green ♦: global constrained optimizer. Numbers in black with arrows indicate the number of overlapping points.

we observe that the situation of trapping into an infeasible local optimum occurs to GLISp more frequently than to C-GLISp. However, GLISp can achieve a solution closer

to the constrained optimum than C-GLISp (Table IV) when GLISp successfully identifies the feasible region. This is because more computational budget is then used to get closer to the optimum than to explore other potentially feasible regions as in C-GLISp. For problems where testing an infeasible solution is expensive and/or dangerous, it is better to be conservative and have a less optimal but feasible solution. As a result, C-GLISp is preferred over GLISp under these problem settings.

Overall, the results on the numerical benchmarks show that both C-GLISp and GLISp can approach near-optimal solutions within a small number of function evaluations. In all of the three benchmarks, both C-GLISp and GLISp outperform PBO (Tables III and IV). An explanation for the superior performance of C-GLISp in identifying feasible/satisfactory solutions is that it explicitly leverages feasibility/satisfaction information in the acquisition function, while GLISp and PBO handle unknown constraints only through preference queries.

## V. MPC CALIBRATION

To illustrate the application of C-GLISp to controller calibration, we consider the design of an MPC controller for lane keeping (LK) and obstacle avoidance (OA) in autonomous driving. MPC is employed to command vehicle velocity and steering angle to provide a smooth and safe drive. The same problem was considered in [27] and is extended in this article to handle feasibility and satisfaction constraints.

The design of model predictive controllers requires tuning several knobs, such as the prediction and control horizons, the weight matrices in the cost function, and numerical tolerances in the optimization solver, under hard constraints such as finding solutions within the sample interval of real-time implementation. Thus, it is hard to well define in advance a single quantitative performance index that captures a usually multifaceted desired closed-loop behavior to tune the MPC parameters automatically.

We use C-GLISp to implement an iterative semiautomated calibration procedure (automatic selection of the MPC parameters and human-based qualitative assessment of closed-loop performance), thus avoiding the burden of defining a quantitative index to minimize. The calibrator only needs to express a preference on pairwise comparisons to indicate which of the two MPC tunings has better closed-loop performance. Different from the case study in [27], where we account for the information of feasibility and satisfaction conditions implicitly in the preference query (GLISp) as if they were, implicitly, underlying penalty functions, C-GLISp explicitly considers this information via direct queries as in (1) and (2).

## A. System Description

We consider a simplified two-degree-of-freedom bicycle model with the front wheel as the reference point to describe the vehicle dynamics and simulate the experiment. The state variables  $s = [x_f \ w_f \ \theta]'$  in the model are the longitudinal  $x_f$  and lateral  $w_f$  (m) positions of the front wheel and the yaw angle  $\theta$  (rad). The manipulated variables  $u = [v \ \psi]'$  are the commanded vehicle velocity v (m/s) and steering

angle  $\psi$  (rad). The standard kinematic equations

$$\dot{x}_f = v \cos(\theta + \psi) 
\dot{w}_f = v \sin(\theta + \psi) 
\dot{\theta} = \frac{v \sin(\psi)}{L}$$
(22)

are used to model the evolution of the vehicle, where L (m) is the vehicle length. Here, full-state observation is assumed, i.e., the control output y=s.

#### B. MPC Formulation

The formulation of the semiautomatic MPC calibration process is detailed in [27]. The dynamical model (22) is linearized around its nominal point  $\bar{s}_k = [\bar{x}_{f_k} \ \bar{w}_{f_k} \ \bar{\theta}_k]', \ \bar{u}_k = [\bar{v}_k \ \bar{\psi}_k]', \text{ and } \bar{y}_k = \bar{s}_k \text{ at each time step and discretized with sampling time } T_s, \text{ resulting the following discrete-time statespace model:}$ 

$$\tilde{s}_{k+1} = \begin{bmatrix}
1 & 0 & -\bar{v}_k \sin(\bar{\theta}_k + \bar{\psi}_k) T_s \\
0 & 1 & \bar{v}_k \cos(\bar{\theta}_k + \bar{\psi}_k) T_s \\
0 & 0 & 1
\end{bmatrix} \tilde{s}_k 
+ \begin{bmatrix}
\cos(\bar{\theta}_k + \bar{\psi}_k) T_s & -\bar{v}_k \sin(\bar{\theta}_k + \bar{\psi}_k) T_s \\
\sin(\bar{\theta}_k + \bar{\psi}_k) T_s & \bar{v}_k \cos(\bar{\theta}_k + \bar{\psi}_k) T_s \\
\frac{\sin(\bar{\psi}_k)}{L} T_s & \frac{\bar{v}_k \cos(\bar{\psi}_k)}{L} T_s
\end{bmatrix} \tilde{u}_k 
\tilde{y}_k = \tilde{s}_k$$
(23)

where subscript k denotes the value at time step k and  $\widetilde{\text{Var}} = \text{Var} - \overline{\text{Var}}$ . This prediction model is then used to design a linear MPC via a real-time iteration scheme [46], [47]. At each sampling time t, the following QP problem is solved to compute the MPC action to be applied:

$$\min_{\{u_{t+k|t}\}_{t=0}^{N_{u-1}}} \sum_{k=0}^{N_{p}-1} \left( \|y_{t+k|t} - y_{t+k}^{\text{ref}}\|_{Q_{y}}^{2} + \|\Delta u_{t+k|t}\|_{Q_{\Delta u}}^{2} \right)$$
(24)

subject to model equation (23) and the following input and output constraints:

$$y_{\min} \le y_{t+k|t} \le y_{\max}, \ k = 1, ..., N_p$$
 $u_{\min} \le u_{t+k|t} \le u_{\max}, \ k = 1, ..., N_p$ 
 $\Delta u_{\min} \le \Delta u_{t+k|t} \le \Delta u_{\max}, \ k = 1, ..., N_p$ 
 $u_{t+N_u+j|t} = u_{t+N_u|t}, \quad j = 1, ..., N_p - N_u$  (25)

where  $\|\cdot\|_M^2$  is the squared norm weighted by a matrix M,  $\Delta u_{t+k|t} = u_{t+k|t} - u_{t+k-1|t}$ ,  $y_{\text{ref}}$  and  $u_{\text{ref}}$  are the reference values of control outputs and inputs during the experiment (which are unique to the LK and OA phases of the experiment), respectively, and  $N_p$  and  $N_u$  are the prediction and control horizons, respectively.

### C. Control Objectives

The two main objectives involved in this control task are: 1) maintaining the vehicle in the same lane with constant speed if no obstacles (other vehicles) are present and 2) passing other moving vehicles if they are within a safety distance. The qualitative descriptions of these objectives, such as the ambiguity of transferring "optimal OA" into a mathematical

formula, make it challenging to define a proper quantitative performance index for closed-loop performance. On the other hand, it is easier for a calibrator to compare the outcome of two different driving tests and then express a preference.

We describe the test scenario as follows. Note that, for ease of assessment, the units of v and  $\psi$  described in the following as well as in the figures are represented in km/h and degree (°), respectively. The controlled vehicle is initially at position  $(x_f,$  $w_f$ ) = (0, 0) m with  $\theta$  = 0°. Another vehicle (obstacle) is at position (30, 0) m and moving horizontally at a constant speed of 40 km/h. The shape of both vehicles is assumed to be rectangular, with a length of 4.5 m and a width of 1.8 m. During the nominal LK conditions, the vehicle being controlled moves horizontally at 50 km/h, with  $w_f = 0$  m and  $\dot{w}_f = 0$  m/s. Once the obstacle is within a safety distance, the vehicle being controlled should pass it while keeping a safe lateral distance between them. In this case, the horizontal and lateral safety distances are 10 and 3 m, respectively. The vehicle controlled by MPC can vary its velocity in the range of [40, 70] km/h during the LK period and [50, 70] km/h during the OA period, and its reference velocities are set to 50 and 60 km/h, respectively. For both LK and OA periods,  $\theta$  can take values in the range of  $[-45^{\circ}, 45^{\circ}]$ , with its rate of change between each time step limited to  $[-5^{\circ}, 5^{\circ}]$ .

The following MPC design parameters are tuned: sampling time  $(T_s)$ , prediction and control horizons  $(N_p, N_u)$ , and weight matrix  $Q_{\Delta u}$  in (24). The sampling time is restricted in the interval [0.085, 0.5] s. The prediction horizon is an integer allowed to vary in the range [10, 30] and the control horizon is taken as a fraction  $\epsilon_c$  of  $N_p$  rounded up to the closest integer, with  $\epsilon_c \in [0.1, 1]$ . The weight matrix is set to be diagonal  $Q_{\Delta u} = \begin{bmatrix} q_{u11} & 0 \\ 0 & q_{u22} \end{bmatrix}$  and the values of  $\log(q_{u11})$  and  $\log(q_{u22})$  are restricted in the interval [-5, 3]. The rest of the MPC design parameter is fixed, with  $Q_y = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}$ .

## D. Calibration Process

The first author of this article plays the role of the calibrator for this case study. The maximum number of function evaluations  $N_{\rm max}$  is set to 50, with  $N_{\rm init}=10$ . The default hyperparameters  $\delta_E$ ,  $\delta_G$ , and  $\delta_S$  in (18) are set to 1, 1, and 0.5, respectively. The parameters  $\sigma$ ,  $c_h$ , and  $\lambda$  in (15) are set to 0.02, 1, and  $1e^{-6}$ , respectively. The hyperparameter  $\epsilon$  characterizing the RBF function (12) is initialized to 1.0 and recalibrated at iterations 10, 20, 30, and 40 via threefold cross validation.

The closed-loop experiment of the vehicle control is simulated for 15 s. Fig. 3 shows the query window for one iteration of the calibration process. The MPC design parameters and the worst case computational time  $(t_{\text{comp}})$  required for solving the QP problem of MPC (24) are displayed at the top of the figure. At each iteration, the calibrator is asked to decide whether the newly proposed experiment is feasible and/or satisfactory and to express a preference between the new experiment and the current best one. More specifically, the calibrator labels the control policy that leads to "unstable/unsafe" and "unimplementable" behavior as infeasible (i.e., G(x) = 0). Examples of

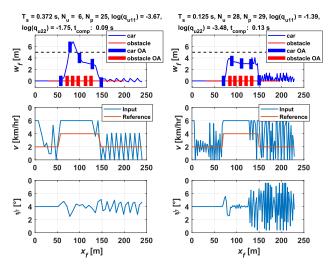

Fig. 3. Vehicle control query window. The top subplots show the vehicle and obstacle positions. The "vehicle OA" and "obstacle OA" bars show five relative positions of the vehicle and obstacle during the OA period. The dashed lines indicate the lateral distance that the car should avoid exceeding (5 m in this case). The middle subplots show the actual and reference velocity  $\boldsymbol{v}$  at different longitudinal positions. The steering angle  $\psi$  over the longitudinal position is shown in the bottom subplots. The results on the left are preferred and feasible, while the results on the right are infeasible. The results on both sets fail to satisfy the satisfaction conditions.

"unstable/unsafe" behaviors include but are not limited to: vehicle hits the obstacle, vehicle oscillates on the road, and so on. "Unimplementable" cases are the ones whose computational time  $(t_{\text{comp}})$  required for solving the QP problem of MPC (24) exceeds the sampling time  $T_s$ . As for being labeled as satisfactory, the following two criteria are used: 1) the lateral position of the vehicle does not exceed 5 m during the OA period (black dashed line on Fig. 3) and 2) the vehicle does not oscillate during the LK period (in other words, the vehicle moves at a constant speed with  $w_f$  and  $\theta$  close to 0 m and 0°). These feasibility and satisfactory criteria are assumed to be unknown to C-GLISp and are learned based on the expressed feasibility and satisfactory labels.

For the pairwise comparisons, the calibrator expresses her preferences according to the following guidelines: 1) whether it is feasible; 2) whether it is satisfactory; 3) whether the vehicle guarantees passengers' comfort during the OA period, for example, by not changing velocities or moving the lateral position too aggressively; 4) whether the deviations of the vehicle velocity from the reference values are minor in both LK and OA periods; and 5) whether aggressive variations of steering angles are avoided. If a conflict combination among criteria mentioned above appears, criterion 1) has the highest priority, and if the conflict is among criteria 2)-5), the control policy that leads to qualitatively safer driving practice based on the calibrator's experience is preferred. Note that conditions 3)-5) and the method of judging safe driving practice are mainly qualitative/subjective, and it is difficult to express them in terms of quantitative metrics.

For the example query window shown in Fig. 3, conflicting combinations of the assessing criteria are observed. Compared to the experiment shown in the left of the figure, the experiment shown in the right has more aggressive lateral movements during the OA period. Furthermore, the changes in

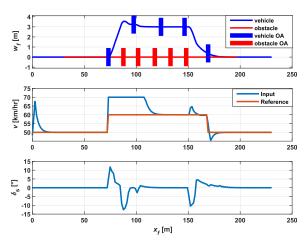

Fig. 4. Final vehicle control performance obtained by the designed MPC controller. The top subplot shows the vehicle and obstacle positions. The "vehicle OA" and "obstacle OA" bars show five relative positions of the vehicle and obstacle during the OA period. The middle subplot shows the actual and reference velocity v at different longitudinal positions. The bottom subplot shows the steering angle  $\psi$  over the longitudinal position.

velocity and steering angle are greater in both frequency and magnitude in both LK and OA periods. The experiment shown in the left is feasible since it is implementable ( $t_{\text{comp}} < T_s$ ) and stable, while the experiment shown in the right of the figure is infeasible since  $t_{\text{comp}}$  exceeds  $T_s$ . In addition, both experiments fail to satisfy the satisfaction conditions. Above all, the performance of the experiment shown in the left is preferred according to criterion 6).

#### E. Results

C-GLISp terminates after 50 simulated closed-loop experiments and 49 pairwise comparisons. The best MPC design parameters  $T_s$ ,  $\epsilon_c$ ,  $N_p$ ,  $\log(q_{u11})$ , and  $\log(q_{u22})$  are 0.085 s, 0.100, 23, -0.323, and -3.71, respectively, with a worst case computation time  $t_{\rm comp}=0.0789$  s. The closed-loop performance obtained via these MPC design parameters is shown in Fig. 4. As shown in the figure, after only 50 simulated experiments, the proposed algorithm can tune the MPC parameters to achieve feasible and satisfactory performance, accomplishing the driving tasks with smooth and safe maneuvers.

## VI. CONCLUSION

The algorithm C-GLISp introduced in this article can handle preference-based global optimization with unknown objective functions and unknown constraints better than other existing black-box surrogate methods (PBO and GLISp), as illustrated through benchmark problems. The autonomous driving case study demonstrated the application of C-GLISp in semiautomated MPC calibration. Although convergence to global optimizers cannot be guaranteed, we observed that the C-GLISp can find satisfactory results within a small number of iterations and that it has a higher probability of proposing feasible samples during the exploration due to the introduction of additional information by the decision-maker that is used to synthesize the corresponding surrogate functions.

Future research will be devoted to exploring different initial sampling methods, warm-starting procedures in the form of "transfer learning" from previous similar optimization runs, and preference-based collective learning to handle multiple decision-makers. We finally note that while we have used C-GLISp for controller calibration, the algorithm can be used in many other applications in which a few tuning parameters must be decided based on preferences under constraints that cannot be easily quantified.

Mengjia Zhu (Member, IEEE) received the B.S. degree in chemical engineering from the University of Washington, Seattle, WA, USA, in 2017, and the M.S. degree in chemical engineering from Imperial College London, London, U.K., in 2019. She is currently pursuing the Ph.D. degree in systems science with the IMT School for Advanced Studies Lucca, Lucca, Italy.

Her current research interest includes black-box optimization and control, with particular emphasis on active, preference, and safe learning.

**Dario Piga** (Member, IEEE) received the Ph.D. degree in systems engineering from the Politecnico di Torino, Turin, Italy, in 2012.

He was an Assistant Professor at the IMT School for Advanced Studies Lucca, Lucca, Italy. Since 2017, he has been a Senior Researcher at the IDSIA Dalle Molle Institute for Artificial Intelligence, Lugano, Switzerland, where he is currently the Founder and the Head of the Learning and Control Group. He has collaborated with international companies and coordinated several research projects

for the development of innovative artificial intelligence (AI)-based systems in the manufacturing, transportation, biomedical, and chemical industries. His main research interests include system identification, control theory, machine learning, and nonlinear optimization.

Dr. Piga is a member of the IEEE-CSS Conference Editorial Board and an Associate Editor of *Automatica* (IFAC Journal).

**Alberto Bemporad** (Fellow, IEEE) received the master's degree in electrical engineering and the Ph.D. degree in control engineering from the University of Florence, Florence, Italy, in 1993 and 1997, respectively.

From 1996 to 1997, he was with the Center for Robotics and Automation, Department of Systems Science and Mathematics, Washington University in St. Louis, St. Louis, MO, USA. From 1997 to 1999, he held a post-doctoral position at the Automatic Control Laboratory, ETH Zürich,

Zürich, Switzerland, where he collaborated as a Senior Researcher until 2002. From 1999 to 2009, he was with the Department of Information Engineering, University of Siena, Siena, Italy, where he became an Associate Professor in 2005. From 2010 to 2011, he was with the Department of Mechanical and Structural Engineering, University of Trento, Trento, Italy. Since 2011, he has been a Full Professor at the IMT School for Advanced Studies Lucca, Lucca, Italy, where he was the Director from 2012 to 2015. He spent visiting periods at Stanford University, Stanford, CA, USA, the University of Michigan, Ann Arbor, MI, USA, and Zhejiang University, Hangzhou, China. In 2011, he co-founded ODYS S.r.l., Milan, Italy, a company specialized in developing model predictive control systems for industrial production. He has published more than 400 articles in the areas of model predictive control, hybrid systems, optimization, and automotive control. He is the co-inventor of 16 patents. He is the author or the coauthor of various software packages for model predictive control design and implementation, including the Model Predictive Control Toolbox (The Mathworks, Inc.) and the Hybrid Toolbox for MATLAB.

Dr. Bemporad received the IFAC High-Impact Paper Award for the 2011–2014 triennial and the IEEE CSS Transition to Practice Award in 2019. He was an Associate Editor of the IEEE TRANSACTIONS ON AUTOMATIC CONTROL from 2001 to 2004 and the Chair of the Technical Committee on Hybrid Systems of the IEEE Control Systems Society from 2002 to 2010.
